## Abstract

Time-varying parameter (TVP) models are widely used in time series analysis to flexibly deal with processes which gradually change over time. However, the risk of overfitting in TVP models is well known. This issue can be dealt with using appropriate global-local shrinkage priors, which pull time-varying parameters towards static ones. In this paper, we introduce the R package `shrinkTVP` ([Knaus, Bitto-Nemling, Cadonna, and Frühwirth-Schnatter 2019](#)), which provides a fully Bayesian implementation of shrinkage priors for TVP models, taking advantage of recent developments in the literature, in particular that of [Bitto and Frühwirth-Schnatter \(2019\)](#). The package `shrinkTVP` allows for posterior simulation of the parameters through an efficient Markov Chain Monte Carlo scheme. Moreover, summary and visualization methods, as well as the possibility of assessing predictive performance through log predictive density scores, are provided. The computationally intensive tasks have been implemented in C++ and interfaced with R. The paper includes a brief overview of the models and shrinkage priors implemented in the package. Furthermore, core functionalities are illustrated, both with simulated and real data.

*Keywords:* Bayesian inference, Gibbs sampler, Markov chain Monte Carlo (MCMC), normal-gamma prior, time-varying parameter (TVP) models, log predictive density scores.

---

## 1. Introduction

Time-varying parameter (TVP) models are widely used in time series analysis, because of their flexibility and ability to capture gradual changes in the model parameters over time. The popularity of TVP models in macroeconomics and finance is based on the fact that, in most applications, the influence of certain predictors on the outcome variables varies over time ([Primiceri 2005; Dangl and Halling 2012; Belmonte, Koop, and Korobilis 2014](#)). TVP models, while capable of reproducing salient features of the data in a very effective way, present a concrete risk of overfitting, as often only a small subset of the parameters are time-varying. Hence, in the last decade, there has been a growing need for models and methods able to discriminate between time-varying and static parameters in TVP models. A key contribution in this direction was the introduction of the non-centered parameterization of TVP models in

Frühwirth-Schnatter and Wagner (2010), which recasts the problem of variance selection and shrinkage in terms of variable selection, thus allowing any tool used to this end in multiple regression models to be used to perform selection or shrinkage of variances. Frühwirth-Schnatter and Wagner (2010) employ a spike and slab prior, while continuous shrinkage priors have been utilised as a regularization alternative in, e.g., Belmonte *et al.* (2014) and Bitto and Frühwirth-Schnatter (2019). For an excellent review of shrinkage priors, with a particular focus on high dimensional regression, the reader is directed to Bhadra, Datta, Polson, and Willard (2017).

In this paper, we describe the R package **shrinkTVP** (Knaus *et al.* 2019) for Bayesian TVP models with shrinkage. The package is available under the general public license (GPL  $\geq 2$ ) from the Comprehensive R Archive Network (CRAN) at <https://cran.r-project.org/web/packages/shrinkTVP>. The package efficiently implements recent developments in the Bayesian literature, in particular the ones presented in Bitto and Frühwirth-Schnatter (2019). The computationally intensive Markov chain Monte Carlo (MCMC) algorithms in the package are written in C++ and interfaced with R (R Core Team 2017) via the **Rcpp** (Eddelbuettel and Balamuta 2017) and the **RcppArmadillo** (Eddelbuettel and Sanderson 2014) packages. This approach combines the ease-of-use of R and its underlying functional programming paradigm with the computational speed of C++.

The package **shrinkTVP** is designed to provide an easy entry point for fitting TVP models with shrinkage priors, while also giving more experienced users the option to adapt the model to their needs. This is achieved by providing a robust baseline model that can be estimated by only passing the data, while also allowing the user to specify more advanced options. Additionally, the **shrinkTVP** package is designed to ensure compatibility with well-known times series formats and to complement other packages. As input objects, time series from the R packages **zoo** (Zeileis and Grothendieck 2005) and **xts** (Ryan and Ulrich 2018) as well as time series formats like **ts** are supported. Estimation output is compatible with the popular R package **coda** (Plummer, Best, Cowles, and Vines 2006) which can be easily applied for convergence diagnostic tests, among others. Coupled with intuitive summary and plot methods, **shrinkTVP** is a package that is easy to use while remaining highly flexible.

**shrinkTVP** is, to our knowledge, the only R package that combines TVP models with shrinkage priors on the time-varying components in a Bayesian framework. Several R packages deal with statistical inference for various specific classes of state space models, of which TVP models are a special case. The most popular R package in this field is **dlm** (Petris 2010), a comprehensive package providing routines for maximum likelihood estimation, Kalman filtering and smoothing, and Bayesian analysis for dynamic linear models (DLMs). The accompanying book (Petris, Petrone, and Campagnoli 2009) introduces the methodology and many R code examples. As of now, priors are not designed to encourage shrinkage and **shrinkTVP** complements **dlm** in this regard.

The R package **bvarsrv** (Krueger 2015) implements Bayesian inference for vector autoregressive (VAR) models with time-varying parameters (TVP-VAR) and stochastic volatility for multivariate time series as introduced by (Primiceri 2005). We refer to (Del Negro and Primiceri 2015) for details on the MCMC algorithm and a later correction of the original scheme. In addition to the very user friendly estimation function **bvar.sv.tvp**, **bvarsrv** provides posterior predictive distributions and enables impulse response analysis. The package includes the macroeconomic data set analysed in (Primiceri 2005) as example data set, **usmacro.update**, which we use in our predictive exercise in Section 5 to showcast the effect of introducing

shrinkage priors on time-varying parameters.

Additional packages emerged very recently. The R package **tvReg** (Casas and Fernandez-Casal 2019) presents a user friendly compendium of many common linear TVP models, including standard linear regression as well as autoregressive, seemingly unrelated equation and VAR models. Estimation is based on kernel smoothing techniques. For an illustrative application, a TVP-VAR(4) model is fitted to the **usmacro.update** data set mentioned above, using the function **tvVAR**. The R package **walker** (Helske 2019) facilitates the estimation of DLMs and generalized DLMs using MCMC algorithms provided by **Stan** (Carpenter, Gelman, Hoffman, Lee, Goodrich, Betancourt, Brubaker, Guo, Li, and Riddell 2017). For inference, the importance sampling method of (Vihola, Helske, and Franks 2017) is implemented within a Hamiltonian Monte Carlo framework. The R package **bsts** (Scott 2019) performs Bayesian analysis for structural time series models, a highly relevant class of state space models including DLMs. **bsts** is a very powerful package that allows shrinkage for static regression coefficients using spike and slab priors. However, as for any other packages mentioned above, variation of the dynamic components is not regularized in **bsts**.

A main contribution of the package **shrinkTVP** is bridging the active field of R packages for state space models with the even more active field of R packages that provide regularization and shrinkage methods for common regression type models. Among others, **ncvreg** (Breheny and Huang 2011) is useful for fitting standard penalized regression estimators, **glmnet** (Friedman, Hastie, and Tibshirani 2010) allows elastic-net regularization for a variety of models, **horseshoe** (van der Pas, Scott, Chakraborty, and Bhattacharya 2016) implements the horseshoe prior, while **shrink** (Dunkler, Sauerbrei, and Heinze 2016) provides various shrinkage methods for linear, generalized linear, and Cox regression models. **biglasso** (Zeng and Breheny 2017) aims at very fast lasso-type regularization for high-dimensional linear regression. Recent R packages include **NormalBetaPrime** (Bai and Ghosh 2019) for Bayesian univariate and **MBSP** (Bai and Ghosh 2018) for Bayesian multivariate linear regression analysis using, respectively, the normal-beta prime and the three parameter beta normal family for inducing shrinkage. The R package **monomvn** (Gramacy 2019) employs a normal-gamma prior in the specific situation of Bayesian inference for multivariate normal and Student-*t* data with a monotone pattern of missing data.

The remainder of the paper is organized as follows. Section 2 briefly introduces TVP models and normal-gamma shrinkage priors, and describes the MCMC algorithm for posterior simulation. The package **shrinkTVP** is introduced in Section 3. In particular, we illustrate how to run the MCMC sampler using the main function **shrinkTVP**, how to choose a specific model, and how to conduct posterior inference using the return object of **shrinkTVP**. Section 4 explains how to assess model performance by calculating log predictive density scores (LPDSs), and how to use LPDSs to compare the predictive performances of different priors. This is illustrated using the **usmacro.update** data set. Finally, Section 6 concludes the paper.

## 2. Model specification and estimation

## 2.1. TVP models

Let us recall the state space form of a TVP model. For  $t = 1, \dots, T$ , we have that

$$\begin{aligned} y_t &= \mathbf{x}_t \boldsymbol{\beta}_t + \epsilon_t, & \epsilon_t &\sim \mathcal{N}(0, \sigma_t^2), \\ \boldsymbol{\beta}_t &= \boldsymbol{\beta}_{t-1} + \mathbf{w}_t, & \mathbf{w}_t &\sim \mathcal{N}_d(0, \mathbf{Q}), \end{aligned} \quad (1)$$

where  $y_t$  is a univariate response variable and  $\mathbf{x}_t = (x_{t1}, x_{t2}, \dots, x_{td})$  is a  $d$ -dimensional row vector containing the regressors at time  $t$ , with  $x_{t1}$  corresponding to the intercept. For simplicity, we assume here that  $\mathbf{Q} = \text{Diag}(\theta_1, \dots, \theta_d)$  is a diagonal matrix, implying that the state innovations are conditionally independent. Moreover, we assume the initial value follows a normal distribution, i.e.,  $\boldsymbol{\beta}_0 \sim \mathcal{N}_d(\boldsymbol{\beta}, \mathbf{Q})$ , with initial mean  $\boldsymbol{\beta} = (\beta_1, \dots, \beta_d)$ . Model (1) can be rewritten equivalently in the non-centered parametrization as

$$\begin{aligned} y_t &= \mathbf{x}_t \boldsymbol{\beta} + \mathbf{x}_t \text{Diag}(\sqrt{\theta_1}, \dots, \sqrt{\theta_d}) \tilde{\boldsymbol{\beta}}_t + \epsilon_t, & \epsilon_t &\sim \mathcal{N}(0, \sigma_t^2), \\ \tilde{\boldsymbol{\beta}}_t &= \tilde{\boldsymbol{\beta}}_{t-1} + \tilde{\mathbf{u}}_t, & \tilde{\mathbf{u}}_t &\sim \mathcal{N}_d(0, I_d), \end{aligned} \quad (2)$$

with  $\tilde{\boldsymbol{\beta}}_0 \sim \mathcal{N}_d(\mathbf{0}, I_d)$ , where  $I_d$  is the  $d$ -dimensional identity matrix.

**shrinkTVP** is capable of modelling the observation error both homoscedastically, i.e.,  $\sigma_t^2 \equiv \sigma^2$  for all  $t = 1, \dots, T$  and heteroscedastically, via a stochastic volatility (SV) specification. In the latter case, the log-volatility  $h_t = \log \sigma_t^2$  follows an AR(1) model (Jacquier, Polson, and Rossi 1994; Kastner and Frühwirth-Schnatter 2014; Kastner 2016). More specifically,

$$h_t | h_{t-1}, \mu, \phi, \sigma_\eta^2 \sim \mathcal{N}(\mu + \phi(h_{t-1} - \mu), \sigma_\eta^2), \quad (3)$$

with initial state  $h_0 \sim \mathcal{N}(\mu, \sigma_\eta^2 / (1 - \phi^2))$ . The stochastic volatility model on the errors can prevent the detection of spurious variations in the TVP coefficients (Nakajima 2011; Sims 2001) by capturing some of the variability in the error term.

## 2.2. Prior Specification

### Shrinkage priors on variances and model parameters

We place conditionally independent normal-gamma priors (Griffin and Brown 2010) both on the standard deviations of the innovations, that is the  $\sqrt{\theta_j}$ 's, and on the means of the initial value  $\beta_j$ , for  $j = 1, \dots, d$ . Note that, in the case of the standard deviations, this can equivalently be seen as a double gamma prior on the innovation variances  $\theta_j$ , for  $j = 1, \dots, d$ . This prior can be represented as a conditionally normal distribution, with the component specific variance following a gamma distribution, that is

$$\sqrt{\theta_j} | \xi_j^2 \sim \mathcal{N}(0, \xi_j^2), \quad \xi_j^2 | a^\xi, \kappa^2 \sim \mathcal{G}\left(a^\xi, \frac{a^\xi \kappa^2}{2}\right), \quad (4)$$

$$\beta_j | \tau_j^2 \sim \mathcal{N}(0, \tau_j^2), \quad \tau_j^2 | a^\tau, \lambda^2 \sim \mathcal{G}\left(a^\tau, \frac{a^\tau \lambda^2}{2}\right). \quad (5)$$

The prior variances  $\xi_j^2$  and  $\tau_j^2$  are referred to as local shrinkage parameters, in that they control the strength with which each individual parameter  $\sqrt{\theta_j}$  and  $\beta_j$  is pulled toward zero.

The parameters  $\kappa^2$  and  $\lambda^2$  are dubbed global shrinkage parameters, as they determine how strongly all parameters are pulled to zero. Since  $E(\theta_j|a^\xi, \kappa^2) = 2/\kappa^2$  and  $E(\beta_j^2|a^\tau, \lambda^2) = 2/\lambda^2$ , the larger  $\kappa^2$  and  $\lambda^2$ , the stronger this effect. Finally, we refer to  $a^\xi$  and  $a^\tau$  as shrinkage adaption parameters. As  $a^\xi$  and  $a^\tau$  decrease, marginally more mass is placed around zero and jointly more mass is put on sparse specifications of the model. In particular, setting the local adaption parameters,  $a^\xi$  and  $a^\tau$ , equal to one results in a Bayesian Lasso (Park and Casella 2008) prior on the  $\sqrt{\theta}_j$ 's and the  $\beta_j$ 's, respectively.

The parameters  $\kappa^2$ ,  $\lambda^2$ ,  $a^\xi$ ,  $a^\tau$  can be learned from the data through appropriate prior distributions. As priors for the global shrinkage parameters, we use

$$\kappa^2 \sim \mathcal{G}(d_1, d_2), \quad \lambda^2 \sim \mathcal{G}(e_1, e_2). \quad (6)$$

Moreover, in order to learn the shrinkage adaption parameters, we generalize the approach taken in Bitto and Frühwirth-Schnatter (2019) and place the following gamma distributions as priors:

$$a^\xi \sim \mathcal{G}(\nu^\xi, \nu^\xi b^\xi), \quad a^\tau \sim \mathcal{G}(\nu^\tau, \nu^\tau b^\tau), \quad (7)$$

which correspond to the exponential priors used in Bitto and Frühwirth-Schnatter (2019) when  $\nu^\xi = 1$  and  $\nu^\tau = 1$ . The parameters  $\nu^\xi$  and  $\nu^\tau$  act as degrees of freedom and allow the prior to be bounded away from zero.

### Prior on the volatility parameter

In the homoscedastic case we employ a hierarchical prior, where the scale of an inverse gamma prior for  $\sigma^2$  follows a gamma distribution, that is,

$$\sigma^2 | C_0 \sim \mathcal{G}^{-1}(c_0, C_0), \quad C_0 \sim \mathcal{G}(g_0, G_0), \quad (8)$$

with hyperparameters  $c_0$ ,  $g_0$ , and  $G_0$ .

In the case of stochastic volatility, the priors on the parameters  $\mu$ ,  $\phi$  and  $\sigma_\eta^2$  in Equation (3) are chosen as in Kastner and Frühwirth-Schnatter (2014), that is

$$\mu \sim \mathcal{N}(b_\mu, B_\mu), \quad \frac{\phi + 1}{2} \sim \mathcal{B}(a_\phi, b_\phi), \quad \sigma_\eta^2 \sim \mathcal{G}(1/2, 1/2B_\sigma), \quad (9)$$

with hyperparameters  $b_\mu$ ,  $B_\mu$ ,  $a_\phi$ ,  $b_\phi$ , and  $B_\sigma$ .

### 2.3. MCMC sampling algorithm

The package **shrinkTVP** implements an MCMC Gibbs sampling algorithm with Metropolis-Hastings steps to obtain draws from the posterior distribution of the model parameters. Here, we roughly sketch the sampling algorithm and refer the interested reader to Bitto and Frühwirth-Schnatter (2019) for further details.

**Algorithm 1** Gibbs Sampling Algorithm

1. Sample the latent states  $\tilde{\beta} = (\tilde{\beta}_0, \dots, \tilde{\beta}_T)$  in the non-centered parametrization from a multivariate normal distribution;
2. Sample jointly  $\beta_1, \dots, \beta_d$ , and  $\sqrt{\theta_1}, \dots, \sqrt{\theta_d}$  in the non-centered parametrization from a multivariate normal distribution;
3. Perform an ancillarity-sufficiency interweaving step and redraw each  $\beta_1, \dots, \beta_d$  from a normal distribution and each  $\theta_1, \dots, \theta_d$  from a generalized inverse Gaussian distribution using **GIGrvg** (Leydold and Hörmann 2017);
4. (a) Sample the variance shrinkage adaption parameter  $a^\xi$  using a random walk Metropolis-Hastings step;  
 (b) Sample the parameter shrinkage adaption parameter  $a^\tau$  using a random walk Metropolis-Hastings step;
5. (a) Sample the local shrinkage parameters  $\xi_j^2$ , for  $j = 1, \dots, d$ , from conditionally independent generalized inverse Gaussian distributions;  
 (b) Sample the local shrinkage parameters  $\tau_j^2$ , for  $j = 1, \dots, d$ , from conditionally independent generalized inverse Gaussian distributions;
6. Sample the error variance  $\sigma^2$  from an inverse gamma distribution in the homoscedastic case or, in the SV case, sample the level  $\mu$ , the persistence  $\phi$ , the volatility of the volatility  $\sigma_\eta^2$  and the log-volatilities  $\mathbf{h} = (h_0, \dots, h_T)$  using **stochvol** (Kastner 2016).

When fitting the model under the full hierarchical shrinkage prior defined in Equations (4)–(7), all steps in Algorithm 1 are performed, while steps 4(a), 4(b), 5(a) and 5(b) are skipped in certain prior setups.

One key feature of the algorithm is the joint sampling of the time-varying parameters  $\tilde{\beta}_t$ , for  $t = 0, \dots, T$  in step 1 of Algorithm 1. We employ the procedure described in McCausland, Miller, and Pelletier (2011) which exploits the sparse, block tri-diagonal structure of the precision matrix of the full conditional distribution of  $\tilde{\beta} = (\tilde{\beta}_0, \dots, \tilde{\beta}_T)$ , to speed up computations.

Moreover, as described in Bitto and Frühwirth-Schnatter (2019), in step 3 we make use of the ancillarity-sufficiency interweaving strategy (ASIS) introduced by Yu and Meng (2011). ASIS is well known to improve mixing by sampling certain parameters both in the centered and non-centered parameterization. This strategy has been successfully applied to univariate SV models (Kastner and Frühwirth-Schnatter 2014), multivariate factor SV models (Kastner, Frühwirth-Schnatter, and Lopes 2017) and dynamic linear state space models (Simpson, Niemi, and Roy 2017).

### 3. The **shrinkTVP** package

#### 3.1. Running the model

The core function of the package **shrinkTVP** is the function **shrinkTVP**, which serves as an R-wrapper for the actual sampler coded in C++. The function works out-of-the-box, meaning

that estimation can be performed with minimal user input. With default settings, the TVP model in Equation (1) is estimated in a Bayesian fashion with priors (4) to (7) and the following choice for the hyperparameters:  $d_1 = d_2 = e_1 = e_2 = 0.001$ ,  $\nu^\xi = \nu^\tau = 5$  and  $b^\xi = b^\tau = 10$ , implying a prior mean of  $E(a^\xi) = E(a^\tau) = 0.1$ . The error is assumed to be homoscedastic, with prior defined in Equation (8) and hyperparameters  $c_0 = 2.5$ ,  $g_0 = 5$ , and  $G_0 = g_0/(c_0 - 1)$ .

The only compulsory argument is an object of class “formula”, which most users will be familiar with (see, for example, the use in the function `lm` in the package **stats** (R Core Team 2017)). The second argument is an optional data frame, containing the response variable and the covariates. Exemplary usage of this function is given in the code snippet below, along with the default output. All code was run on a personal computer with an Intel i5-8350U CPU.

```
R> library("shrinkTVP")
R>
R> # Baseline model
R> set.seed(123)
R> sim <- simTVP(theta = c(0.2, 0, 0), beta_mean = c(1.5, -0.3, 0))
R> data <- sim$data
R> res <- shrinkTVP(y ~ x1 + x2, data = data)

0%   10%   20%   30%   40%   50%   60%   70%   80%   90%   100%
[----|----|----|----|----|----|----|----|----|----|----|
*****|*****|*****|*****|*****|*****|*****|*****|*****|*****|*****|
```

Timing (elapsed): 4.647 seconds.

Note that the data in the example is generated by the function `simTVP`, which can create synthetic datasets of varying sizes for illustrative purposes. The inputs `theta` and `beta` can be used to specify the true  $\theta_1, \dots, \theta_d$  and  $\beta_1, \dots, \beta_d$  used in the data generating process, in order to evaluate how well `shrinkTVP` recaptures these true values. The values correspond to the ones used in the synthetic example of [Bitto and Frühwirth-Schnatter \(2019\)](#).

The user can specify the following MCMC algorithm parameters: `niter`, which determines the number of MCMC iterations including the burn-in, `nburn`, which equals the number of MCMC iterations discarded as burn-in, and `nthin`, indicating the thinning parameter, meaning that every `nthin`-th draw is kept and returned. The default values are `niter = 10000`, `nburn = round(niter/2)` and `nthin = 1`.

The user is strongly encouraged to check convergence of the produced Markov chain, especially for a large number of covariates. The output is made **coda** compatible, so that the user can utilize the tools provided by the excellent R package to assess convergence.

### 3.2. Specifying the priors

More granular control over the prior setup can be exercised by specifying all or a subset of the parameters. In addition to changing the hyperparameters given in Section 2.2, the user

	Shrinkage on $\sqrt{\theta_j}$		Shrinkage on $\beta_j$	
	$a^\xi$	$\kappa^2$	$a^\tau$	$\lambda^2$
Full hierarchical shrinkage prior	$\mathcal{G}(\nu^\xi, \nu^\xi b^\xi)$	$\mathcal{G}(d_1, d_2)$	$\mathcal{G}(\nu^\tau, \nu^\tau b^\tau)$	$\mathcal{G}(e_1, e_2)$
Hierarchical normal-gamma prior	fixed	$\mathcal{G}(d_1, d_2)$	fixed	$\mathcal{G}(e_1, e_2)$
Normal-gamma prior	fixed	fixed	fixed	fixed
Bayesian Lasso	fixed at 1	fixed	fixed at 1	fixed

Table 1: Overview of different possible model specifications.

can fix one or both values of the global shrinkage parameters ( $\kappa^2, \lambda^2$ ) and the shrinkage adaption parameters ( $a^\tau, a^\xi$ ), instead of learning them from the data as done in the default setting. The benefit of this is twofold: on the one hand, desired degrees of sparsity and global shrinkage can be achieved through fixing the hyperparameters; on the other hand, interesting special cases arise from setting certain values of hyperparameters. For example, setting the local adaption parameters,  $a^\xi$  and  $a^\tau$ , equal to one results in a Bayesian Lasso (Park and Casella 2008) prior on the  $\sqrt{\theta_j}$ 's and the  $\beta_j$ 's, respectively. If the user desires a higher degree of sparsity, this can be achieved by setting the shrinkage adaption parameters to a value closer to zero. Table 1 gives an overview of different model specifications. Note that separate prior choices can be made for the variances and the means of the initial values.

In the following, we give some examples of models that can be estimated with the **shrinkTVP** package. In particular, we demonstrate how certain combinations of input arguments correspond to different model specifications. Note that in the following snippets of code, the argument `display_progress` is always set to `FALSE`, in order to suppress the progress bar and other outputs.

**Fixing the shrinkage adaption parameters** It is possible to set the shrinkage adaption parameter  $a^\xi(a^\tau)$  to a fixed value through the input argument `a_xi` (`a_tau`), after setting `learn_a_xi` (`learn_a_tau`) to `FALSE`. As an example, we show how to fit a hierarchical Bayesian Lasso, both on the  $\sqrt{\theta_j}$ 's and on the  $\beta_j$ 's:

```
R> res_hierlasso <- shrinkTVP(y ~ x1 + x2, data = data,
+   learn_a_xi = FALSE, learn_a_tau = FALSE,
+   a_xi = 1, a_tau = 1, display_progress = FALSE)
```

**Fixing the global shrinkage parameters** The user can choose to fix the value of  $\kappa^2(\lambda^2)$  by specifying the argument `kappa2` (`lambda2`), after setting `learn_k2` (`learn_lambda2`) to `FALSE`. In the code below, we give an example on how to fit a (non-hierarchical) Bayesian Lasso on both  $\sqrt{\theta_j}$ 's and  $\beta_j$ 's, with corresponding global shrinkage parameters fixed both to 100:

```
R> res_lasso <- shrinkTVP(y ~ x1 + x2, data = data,
+   learn_a_xi = FALSE, learn_a_tau = FALSE, a_xi = 1, a_tau = 1,
+   learn_kappa2 = FALSE, learn_lambda2 = FALSE, kappa2 = 100, lambda2 = 100,
+   display_progress = FALSE)
```

### 3.3. Stochastic volatility specification

The stochastic volatility specification defined in Equation (3) can be used by setting the option `sv` to `TRUE`. This is made possible by a call to the `update_sv` function exposed by the `stochvol` package. The code below fits a model in which all the parameters are learned and the observation equation errors are modeled through stochastic volatility:

```
R> res_sv <- shrinkTVP(y ~ x1 + x2, data = data, sv = TRUE,
+   display_progress = FALSE)
```

The priors on the SV parameters are the ones defined in Equation (9), with hyperparameters fixed to  $b_\mu = 0$ ,  $B_\mu = 1$ ,  $a_\phi = 5$ ,  $b_\phi = 1.5$ , and  $B_\sigma = 1$ .

### 3.4. Specifying the hyperparameters

Beyond simply switching off parts of the hierarchical structure of the prior setup, users can also modify the hyperparameters governing the prior distributions. This can be done through the arguments `hyperprior_param` and `sv_param`, which both have to be named lists.

In addition to user defined hyperparameters, unspecified parameters will be set to default values, as defined in Section 3.2.

```
R> res_hyp <- shrinkTVP(y ~ x1 + x2, data = data,
+   hyperprior_param = list(b_xi = 5, nu_xi = 10),
+   display_progress = FALSE)
```

### 3.5. Posterior inference: Summarize and visualize the posterior distribution

The return value of `shrinkTVP` is an object of type `shrinkTVP`, which is a named list containing a variable number of elements, depending on the prior specification. For the default model, the values are:

1. the parameter draws of  $\sigma^2$  in `sigma2`,
2. the parameter draws of  $(\sqrt{\theta_1}, \dots, \sqrt{\theta_d})$  in `theta_sr`,
3. the parameter draws of  $\beta = (\beta_1, \dots, \beta_d)$  in `beta_mean`,
4. a list holding  $d$  `mcmc.tvp` objects (one for each  $\beta_j = (\beta_{j0}, \dots, \beta_{jT})$ ) containing the parameter draws in `beta`,
5. the parameter draws of  $\xi_1^2, \dots, \xi_d^2$ , in `xi2`,
6. the parameter draws of  $a^\xi$  in `a_xi`,
7. some acceptance statistics for the Metropolis-Hastings step for  $a^\xi$  in `a_xi_acceptance`,
8. the parameter draws of  $\tau_1^2, \dots, \tau_d^2$  in `tau2`,
9. the parameter draws of  $a^\tau$  in `a_tau`,
10. some acceptance statistics for the Metropolis-Hastings step for  $a^\tau$  in `a_tau_acceptance`,

11. the parameter draws for  $\kappa^2$  in `kappa2`,
12. the parameter draws for  $\lambda^2$  in `lambda2`,
13. the parameter draws of  $C_0$  in `C0`,
14. the prior hyperparameters in `priorvals`,
15. the design matrix, the response and the formula in `model`,
16. summary statistics for the parameter draws in `summaries` and objects required for the `LPDS` function in `LPDS_comp`.

When some parameters are fixed by the user, the corresponding output value is omitted. In the SV case, the draws for the parameters of the SV model on the errors are contained in `sv_mu`, `sv_phi` and `sv_sigma`. For details, see [Kastner \(2016\)](#).

The two main tools for summarizing the output of `shrinkTVP` are the `summary` and `plot` methods implemented for `shrinkTVP` objects. `summary` has two arguments beyond the `shrinkTVP` object itself, namely `digits` and `showprior`, which control the output displayed. `digits` indicates the number of decimal places to round the posterior summary statistics to, while `showprior` determines whether or not to show the prior distributions resulting from the user input. In the example below, the default `digits` value of 3 is used, while the prior specification is omitted. The output of `summary` consists of the mean, standard deviation, median, 95% highest posterior density region and effective sample size (ESS) for the non time-varying parameters.

The `plot` method can be used to visualize the posterior distribution estimated by `shrinkTVP`. Aside from a `shrinkTVP` object, its main argument is `pars`, a character vector containing the names of the parameters to visualize. `plot` will call either `plot.mcmc.tvp` from the `shrinkTVP` package if the parameter is time-varying or `plot.mcmc` from the `coda` package, if the parameter is non time-varying. The default value of `pars` is `c("beta")`, leading to `plot.mcmc.tvp` being called on each of the  $\beta_{jt}$ , for  $j = 1, \dots, d$ . See the code below for an example and Figure 1 for the corresponding output.

```
R> plot(res)
```

The `plot.mcmc.tvp` method displays empirical posterior credible intervals of a time-varying parameter over time, i.e.,  $\beta_{jt}$ , for  $j = 1, \dots, d$  and  $\sigma_t^2$  in the case of stochastic volatility. By default, the pointwise 95% and 50% posterior credible intervals are displayed as shaded areas layered on top of one another, with the median represented by a black line, with an additional grey, dashed line at zero. To ensure that users have flexibility in the plots created, a host of options are implemented for customisation. The bounds of the credible intervals can be modified through the `probs` input, allowing for different levels of uncertainty visualization. The arguments `quantlines` and `shaded` take boolean vectors as inputs, and determine if the corresponding credible intervals will be displayed through shading and/or lines. The shaded areas can be customised via the arguments `shadecol` and `shadealpha`, which determine the color and the degree of transparency of the shaded areas. The lines representing the quantiles can be adjusted through `quantlty`, `quantcol` and `quantlwd`, which modify the line type, color and line width, respectively. In the spirit of R, all of these arguments are vectorised and the supplied vectors are recycled in the typical R fashion if necessary. The first element of these vectors is always applied to the outermost credible interval, the second to the second outermost and so forth. The horizontal line at zero can be similarly adjusted through `zerolty`, `zerolwd` and `zerocol` or entirely turned off by setting `drawzero` equal to `FALSE`. All further arguments are passed on to the standard `plot` method, allowing for changes to the line representing the median and other plot modifications that users of R are familiar with. An example of possible customisation can be seen in the code below, with the corresponding output being Figure 2.

```
R> plot(res, pars = "beta", xlim = c(100, 200),
+       probs = seq(0.1, 0.9, by = 0.1),
+       quantlines = T, quantcol = color[c(1:4, 4:1)], quantlty = 1,
+       quantlwd = 3, col = color[5], lwd = 3, shadecol = "gold1")
```

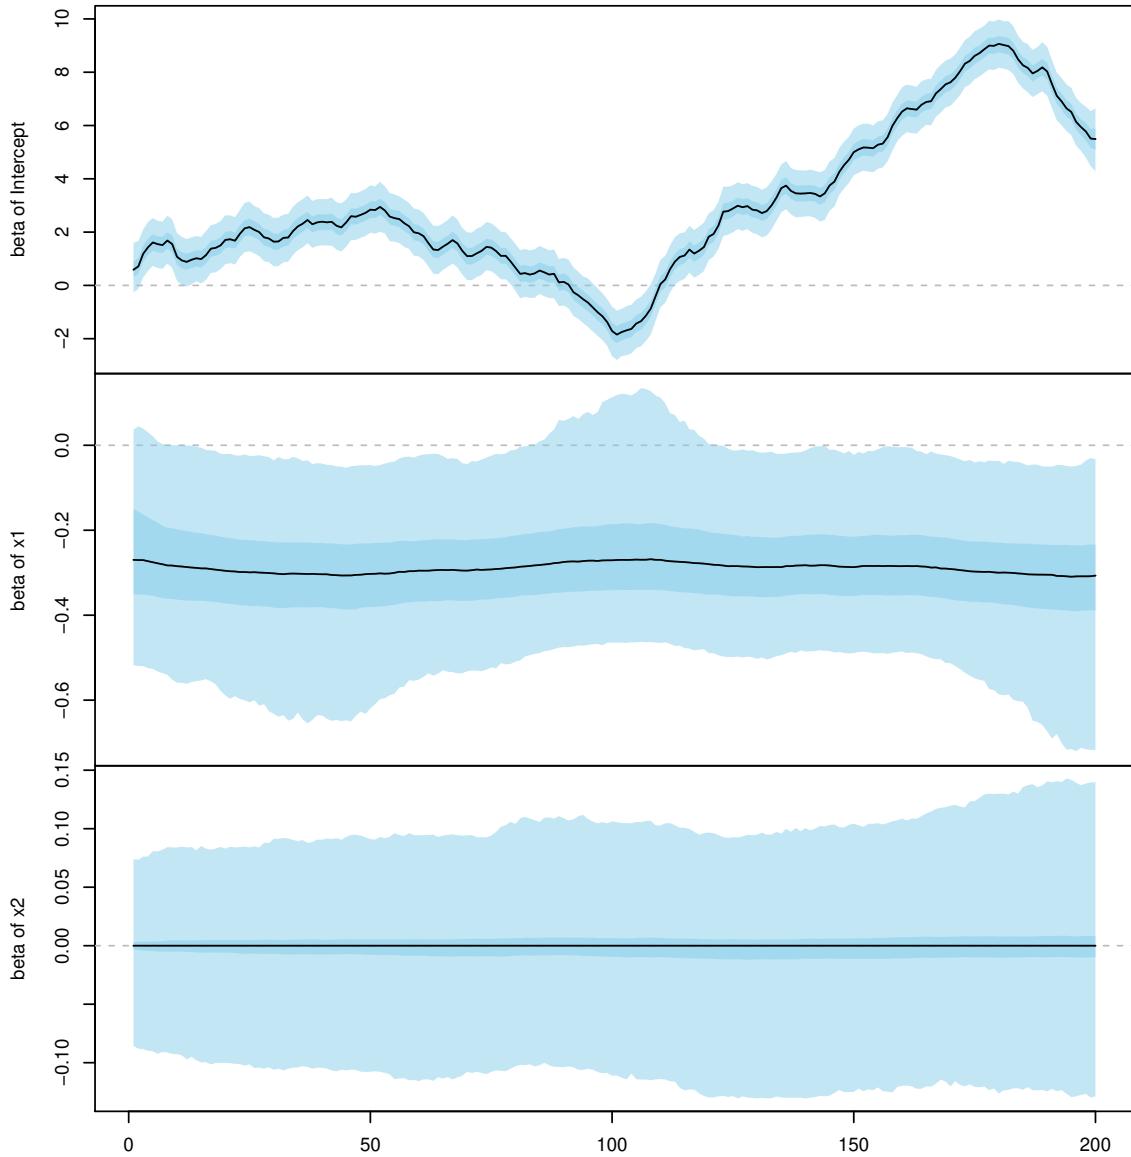

Figure 1: Visualization of the evolution of the time-varying parameter  $\beta_j = (\beta_{j0}, \dots, \beta_{jT})$ ,  $j = 1, 2, 3$ , over time  $t = 0, \dots, T$ , as provided by the `plot` method. `plot` is in turn calling `plot.mcmc.tvp` on the individual `mcmc.tvp` objects. The median is displayed as a black line, and the shaded areas indicate the pointwise 95% and 50% posterior credible intervals.

To visualize other parameters via the `plot` method, the user has to change the `pars` argument. `pars` can either be set to a single character object or to a vector of characters containing the names of the parameter draws to display. In the latter case, the `plot` method will display groups of plots at a time, prompting the user to move on to the next series of plots, similarly to how `coda` handles long plot outputs. Naturally, as all parameter draws are converted to `coda` objects, any method from this package that users are familiar with (e.g., to check convergence) can be applied to the parameter draws contained in a `shrinkTVP` object. An example of this can be seen in Figure 3, where `pars = "theta_sr"`, changes the output to a

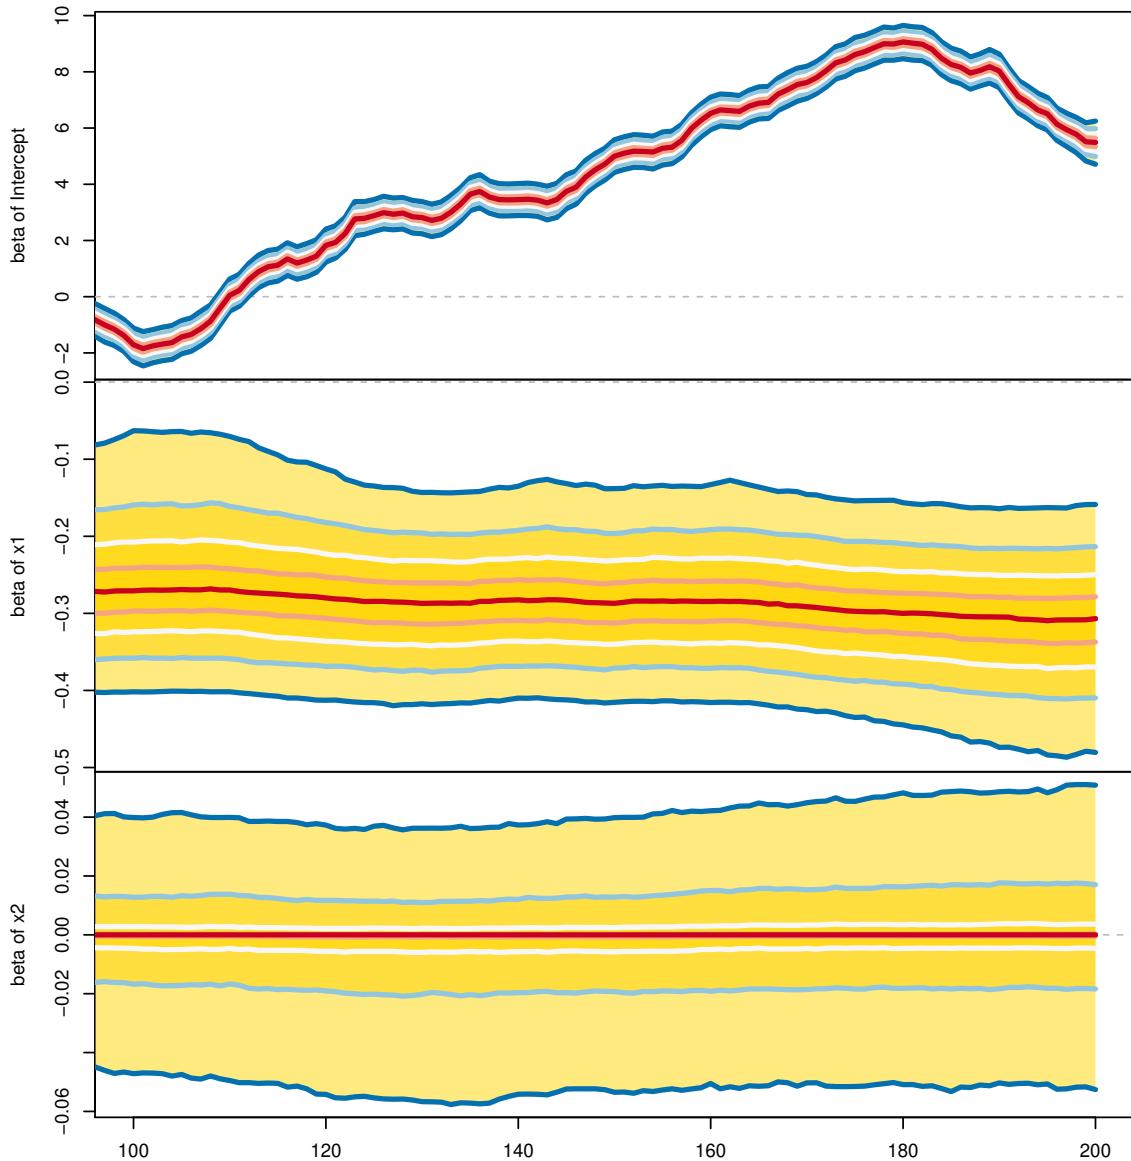

Figure 2: Visualization of the evolution of the time-varying parameter  $\beta_t$  over time  $t = 100, \dots, 200$  for  $j = 1, \dots, 3$ . In this example, the x-axis of the plot was restricted with `xlim`, the color of the shaded areas was changed to yellow and colored solid lines have been added to delimit the credible intervals. The colored lines represent the median and the pointwise 10%, 20%, 30%, 40%, 60%, 70%, 80%, and 90% quantiles.

graphical summary of the parameter draws of  $\sqrt{\theta_1}, \dots, \sqrt{\theta_d}$ , using **coda**'s `plot.mcmc` function. To obtain Figure 3, one can run

```
R> plot(res, pars = "theta_sr")
```

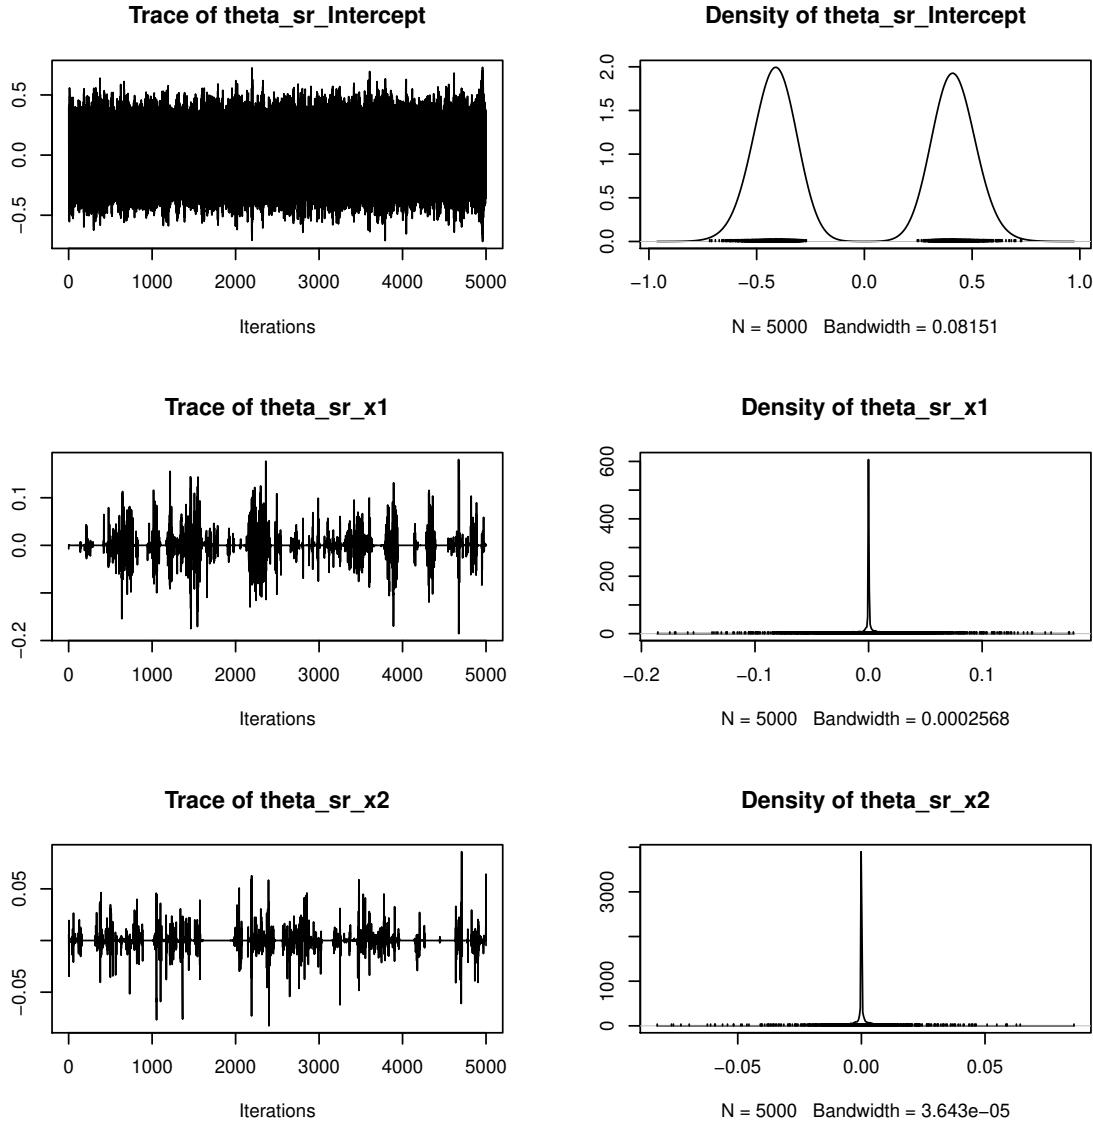

Figure 3: Trace plots (left column) and kernel density estimates of the posterior density (right column) for the parameters  $\sqrt{\theta}_1, \dots, \sqrt{\theta}_3$ , as provided by the `plot` method. `plot` is in turn calling `coda`'s `plot.mcmc`.

## 4. Predictive performances and model comparison

Within a Bayesian framework, a natural way to predict a future observation is through its posterior predictive density. For this reason, log-predictive density scores (LPDSs) provide a means of assessing how well the model performs in terms of prediction on real data. The log-predictive density score for time  $t_0 + 1$  is obtained by evaluating at  $y_{t_0+1}$  the log of the posterior predictive density obtained by fitting the model to the previous  $t_0$  data points.

Given the data up to time  $t_0$ , the posterior predictive density at time  $t_0 + 1$  is given by

$$p(y_{t_0+1}|y_1, \dots, y_{t_0}, \mathbf{x}_{t_0+1}) = \int p(y_{t_0+1}|\mathbf{x}_{t_0+1}, \boldsymbol{\psi})p(\boldsymbol{\psi}|y_1, \dots, y_{t_0})d\boldsymbol{\psi}, \quad (10)$$

where  $\boldsymbol{\psi}$  is the set of model parameters and latent variables up to  $t_0 + 1$ . For a TVP model with homoscedastic errors,  $\boldsymbol{\psi} = (\tilde{\beta}_0, \dots, \tilde{\beta}_{t_0+1}, \sqrt{\theta}_1, \dots, \sqrt{\theta}_d, \beta_1, \dots, \beta_d, \sigma^2)$ , whereas for a TVP model with SV errors,  $\boldsymbol{\psi} = (\tilde{\beta}_0, \dots, \tilde{\beta}_{t_0+1}, \sqrt{\theta}_1, \dots, \sqrt{\theta}_d, \beta_1, \dots, \beta_d, \sigma_1^2, \dots, \sigma_{t_0+1}^2)$ . Given  $M$  samples from the posterior distribution of the parameters and latent variables,  $p(\boldsymbol{\psi}|y_1, \dots, y_{t_0})$ , Monte Carlo integration could be applied immediately to approximate (10). However, Bitto and Frühwirth-Schnatter (2019) propose a more efficient approximation of the predictive density, the so-called conditionally optimal Kalman mixture approximation which is obtained by analytically integrating out  $\tilde{\beta}_{t_0+1}$  from the likelihood at time  $t_0 + 1$ .

In the homoscedastic error case, given  $M$  samples from the posterior distribution of the parameters and the latent variables up to  $t_0$ , Monte Carlo integration of the resulting predictive density yields following mixture approximation,

$$\begin{aligned} p(y_{t_0+1}|y_1, \dots, y_{t_0}, \mathbf{x}_{t_0+1}) &\approx \frac{1}{M} \sum_{m=1}^M f_{\mathcal{N}}(y_{t_0+1}; \hat{y}_{t_0+1}^{(m)}, S_{t_0+1}^{(m)}), \\ \hat{y}_{t_0+1}^{(m)} &= \mathbf{x}_{t_0+1}\boldsymbol{\beta}^{(m)} + \mathbf{F}_{t_0+1}^{(m)}\mathbf{m}_{t_0}^{(m)}, \\ S_{t_0+1}^{(m)} &= \mathbf{F}_{t_0+1}^{(m)}(\boldsymbol{\Sigma}_{t_0}^{(m)} + I_d)(\mathbf{F}_{t_0+1}^{(m)})^\top + (\sigma^2)^{(m)}, \end{aligned} \quad (11)$$

where the conditional predictive densities are Gaussian and the conditional moments depend on the MCMC draws. The mean  $\hat{y}_{t_0+1}^{(m)}$  and the variance  $S_{t_0+1}^{(m)}$  are computed for the  $m$ th MCMC iteration from  $\mathbf{F}_{t_0+1} = \mathbf{x}_{t_0+1}\text{Diag}(\sqrt{\theta}_1, \dots, \sqrt{\theta}_d)$  and the mean  $\mathbf{m}_{t_0}$  and the covariance matrix  $\boldsymbol{\Sigma}_{t_0}$  of the posterior distribution of  $\tilde{\beta}_{t_0}$ . These quantities can be obtained by iteratively calculating  $\boldsymbol{\Sigma}_t$  and  $\mathbf{m}_t$  up to time  $t_0$ , as described in McCausland *et al.* (2011):

$$\begin{aligned} \boldsymbol{\Sigma}_1 &= (\boldsymbol{\Omega}_{11})^{-1}, \quad \mathbf{m}_1 = \boldsymbol{\Sigma}_1\mathbf{c}_1, \\ \boldsymbol{\Sigma}_t &= (\boldsymbol{\Omega}_{tt} - \boldsymbol{\Omega}_{t-1,t}^\top \boldsymbol{\Sigma}_{t-1} \boldsymbol{\Omega}_{t-1,t})^{-1}, \quad \mathbf{m}_t = \boldsymbol{\Sigma}_t(\mathbf{c}_t - \boldsymbol{\Omega}_{t-1,t}^\top \mathbf{m}_{t-1}). \end{aligned}$$

The quantities  $\mathbf{c}_t$ ,  $\boldsymbol{\Omega}_{tt}$  and  $\boldsymbol{\Omega}_{t-1,t}$  for  $t = 1, \dots, t_0$  are given in Appendix A.

For the SV case, it is still possible to analytically integrate out  $\tilde{\beta}_{t_0+1}$  from the likelihood at time  $t_0 + 1$  conditional on a known value of  $\sigma_{t_0+1}^2$ , however it is not possible to integrate the likelihood with respect to both latent variables  $\tilde{\beta}_{t_0+1}$  and  $\sigma_{t_0+1}^2$ . Hence, at each MCMC iteration a draw is taken from the predictive distribution of  $\sigma_{t_0+1}^2 = \exp(h_{t_0+1})$ , derived from Equation (3), and used to calculate the conditional predictive density of  $y_{t_0+1}$ . The approximation of the one-step ahead predictive density can then be obtained through the following steps:

1. for each MCMC draw of  $(\mu, \phi, \sigma_\eta^2)^{(m)}$  and  $h_{t_0}^{(m)}$ , obtain a draw of  $(\sigma_{t_0+1}^2)^{(m)}$ ;
2. calculate the conditionally optimal Kalman mixture approximation as in (11) with following slightly different values  $S_{t_0+1}^{(m)}$ :

$$S_{t_0+1}^{(m)} = \mathbf{F}_{t_0+1}^{(m)}(\boldsymbol{\Sigma}_{t_0}^{(m)} + I_d)(\mathbf{F}_{t_0+1}^{(m)})^\top + (\sigma_{t_0+1}^2)^{(m)},$$

where  $\mathbf{F}_{t_0+1}$  and  $\boldsymbol{\Sigma}_{t_0}$  are the same as defined above.

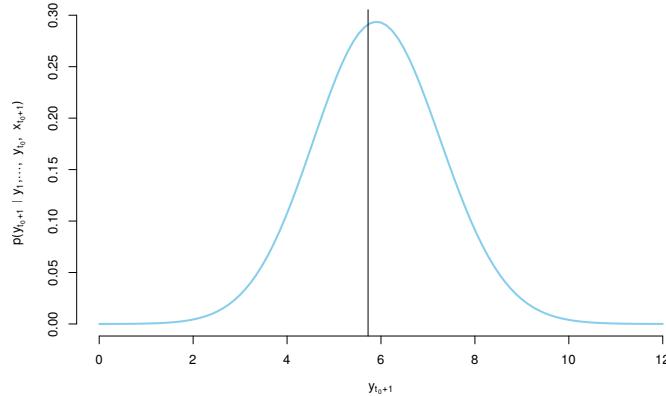

Figure 4: One-step ahead predictive density  $p(y_{t_0+1}|y_1, \dots, y_{t_0}, \mathbf{x}_{t_0+1})$  for a synthetic data set. The black vertical line represents the true realisation of  $y_{t_0+1}$ .

These calculations can be performed by the `LPDS` function, based on a fitted TVP model resulting from a call to `shrinkTVP`. The function's arguments are an object of class `shrinkTVP` and `data_test`, a data frame with one row, containing covariates and response at time  $t_0 + 1$ . The following snippet of code fits a `shrinkTVP` model to synthetic data up to  $T - 1$ , and then calculates the LPDS at time  $T$ . The obtained LPDS score is then displayed. For an example on how to calculate LPDSs for  $k$  points in time, please see Section 5.

```
R> res_LPDS <- shrinkTVP(y ~ x1 + x2, data = data[1:(nrow(data) - 1), ],
+   display_progress = FALSE)
R> LPDS(res_LPDS, data[nrow(data), ])
[1] -1.234404
```

An additional functionality provided by the package `shrinkTVP` is the evaluation of the one-step ahead predictive density through the function `eval_pred_dens`. It takes as inputs an object of class `shrinkTVP`, a one row data frame containing  $\mathbf{x}_{t_0+1}$  and a point, or vector of points, at which the predictive density is to be evaluated. It returns a vector of the same length, containing the value of the density at the points the user supplied. An example of this can be seen in the code below.

```
R> eval_pred_dens(1:3, res_LPDS, data[nrow(data), ])
[1] 0.0003977231 0.0043372607 0.0283156058
```

Thanks to its vectorised nature, `eval_pred_dens` can be plugged directly into functions that expect an expression that evaluates to the length of the input, such as the `curve` function from the `graphics` (R Core Team 2017) package. The following snippet of code exploits this behaviour to plot the posterior predictive density. The result can be seen in Figure 4.

```
R> curve(eval_pred_dens(x, res_LPDS, data[nrow(data), ]), to = 12,
+     ylab = bquote("p(" * y[t[0]+1] * "\uff5c" * y[1] * ", "
+     * ldots * "," ~ y[t[0]] * "," ~ x[t[0]+1] * ")"),
+     xlab = expression(y[t[0]+1]), lwd = 2.5, col = "skyblue", axes = FALSE)
R> abline(v = data$y[nrow(data)])
R> axis(1)
R> axis(2)
```

## 5. Predictive exercise: usmacro dataset

In the following, we provide a brief demonstration on how to use the **shrinkTVP** package on real data and compare different prior specifications via LPDSs. Specifically, we consider the **usmacro.update** dataset from the **bvarsrv** package (Krueger 2015). The dataset **usmacro.update** contains the inflation rate, unemployment rate and treasury bill interest rate for the United States, from 1953:Q1 to 2015:Q2, that is  $T = 250$ . The same dataset up to 2001:Q3 was used by Primiceri (2005). The response variable is the inflation rate **inf**, while the predictors are the lagged inflation rate **inf\_lag**, the lagged unemployed rate **une\_lag** and the lagged treasury bill interest **tbi\_lag**. We construct our dataset as follows:

```
R> library("bvarsrv")
R> data("usmacro.update")
R>
R> # Create matrix of lags and create final data set
R> lags <- usmacro.update[1:(nrow(usmacro.update) - 1), ]
R> colnames(lags) <- paste0(colnames(lags), "_lag")
R> us_data <- data.frame(inf = usmacro.update[2:nrow(usmacro.update), "inf"],
+   lags)
```

In the snippet of code below, we run the default TVP model with the full hierarchical shrinkage prior for 60000 iterations, with a thinning of 10 and a burn-in of 10000, hence keeping 5000 posterior draws.

```
R> us_res <- shrinkTVP(inf ~ inf_lag + une_lag + tbi_lag, us_data,
+   niter = 60000, nburn = 10000, nthin = 10,
+   display_progress = FALSE)
```

Once we have fit the model, we can perform posterior inference by using the **summary** and **plot** methods. The summary is shown below, while Figure 5 shows the paths of  $\beta_t$  evolving over time, and Figure 6 displays the trace plots (left column) and posterior densities (right column) of  $\sqrt{\theta_1}, \dots, \sqrt{\theta_4}$  obtained via the **plot** method.

```
R> summary(us_res, showprior = FALSE)
```

```
Summary of 50000 MCMC draws after burn-in of 10000.
```

It appears clear by looking at Figure 5 that the intercept and the parameter associated with the lagged inflation rate are time-varying, while the parameters associated with the lagged treasury bill interest rate and the lagged unemployment rate are relatively constant. This can be confirmed by looking at the posterior distributions of the corresponding standard deviations, displayed in Figure 6. The posterior densities of the standard deviations associated with the intercept and the lagged inflation are bimodal, with very little mass around zero. This bimodality results from the non-identifiability of the sign of the standard deviation. As a convenient side effect, noticeable bimodality in the density plots of the posterior distribution  $p(\sqrt{\theta_j}|\mathbf{y})$  of the standard deviations  $\sqrt{\theta_j}$  is a strong indication of time variability in the associated parameter  $\beta_{jt}$ . Conversely, the posterior densities of the standard deviations associated with the lagged unemployment and the lagged treasury bill interest rate have a pronounced spike at zero, indicating strong model evidence in favor of constant parameters. Moreover,

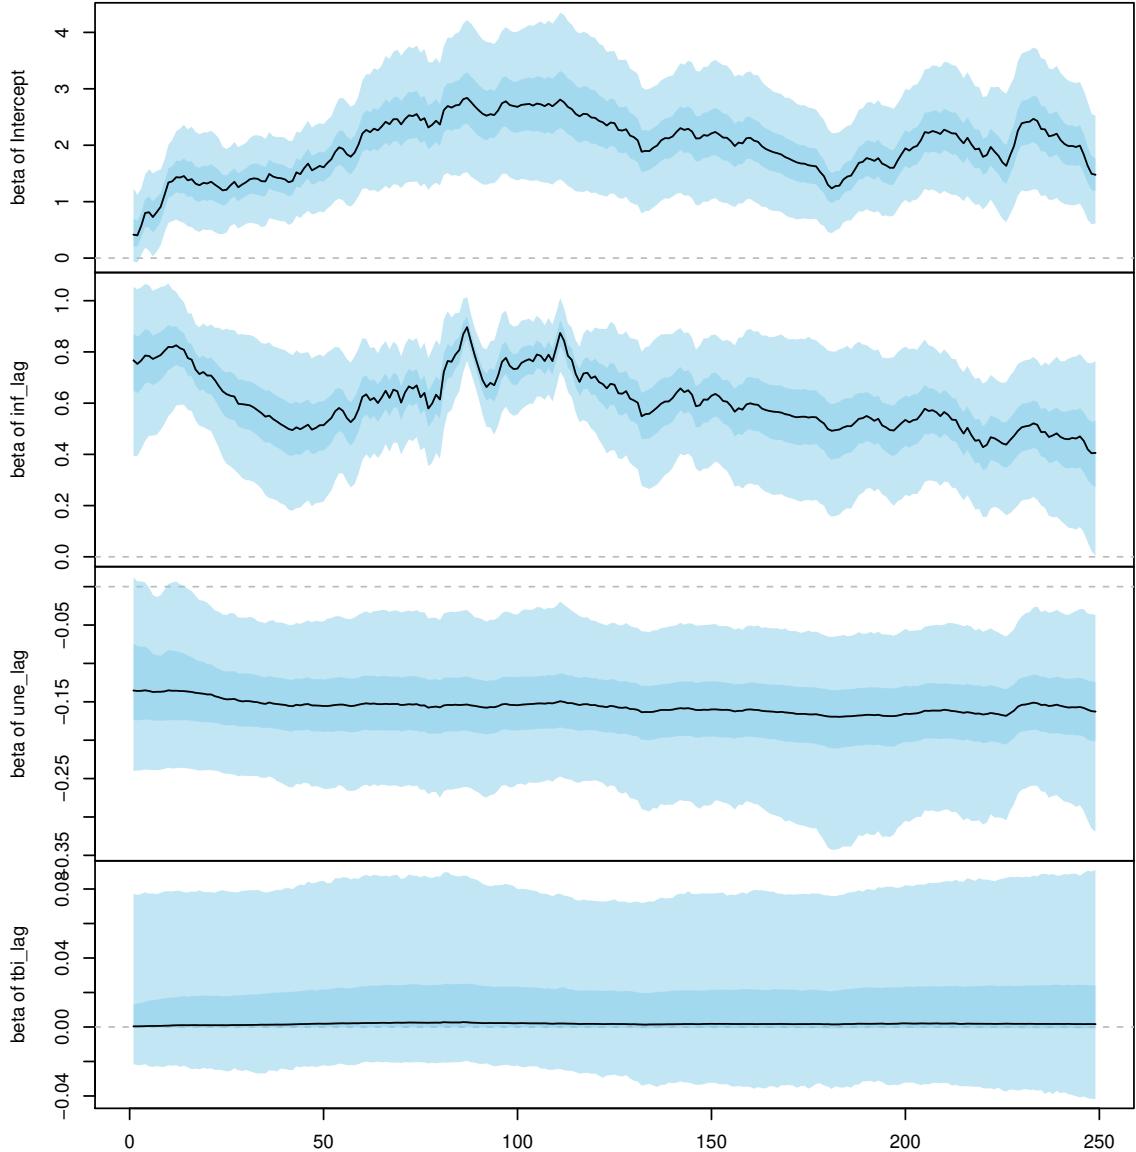

Figure 5: Visualization of the evolution of the time-varying parameter  $\beta_j = (\beta_{j0}, \dots, \beta_{jT})$  over time  $t = 0, \dots, T$  for  $j = 1, \dots, 4$  for the `usmacro.update` dataset. The median is displayed as a black line, and the shaded areas indicate the pointwise 95% and 50% posterior credible intervals.

the path of the parameter of the treasury bill interest rate is centered at zero, indicating that this parameter is neither time-varying nor significant.

In order to compare the predictive performances of different shrinkage priors, we calculate one-step ahead LPDSs for the last 50 points in time for five different prior choices: (1) the full hierarchical shrinkage prior, (2) the hierarchical normal-gamma prior with fixed  $a^\xi = a^\tau = 0.1$ , (3) the normal-gamma prior with  $a^\xi = a^\tau = 0.1$  and  $\kappa^2 = \lambda^2 = 20$ , (4) the hierarchical Bayesian Lasso, and (5) the Bayesian Lasso with  $\kappa^2 = \lambda^2 = 20$ . Figure 7 shows the cumulative LPDSs for the last 50 quarters of the `usmacro.update` dataset. The default prior, that is the

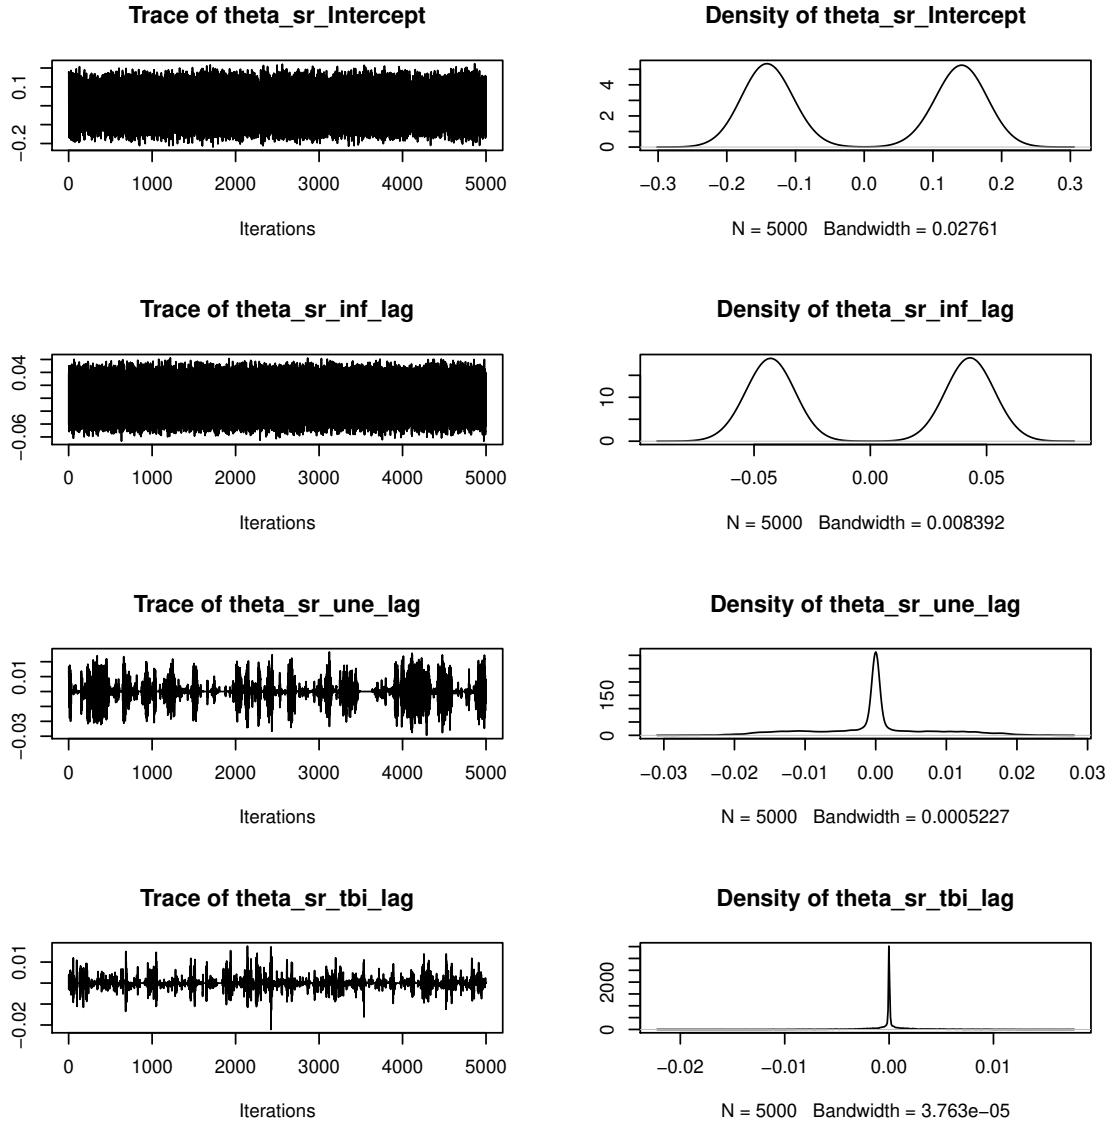

Figure 6: Trace plots (left column) and kernel density estimates of the posterior density (right column) for the `usmacro.update` dataset.

fully hierarchical shrinkage prior on both the  $\beta_j$ 's and the  $\sqrt{\theta_j}$ 's, performs the best in terms of prediction amongst the five fitted models. In Appendix B we show how to obtain LPDSs for different models and points in time, using the packages **foreach** (Microsoft and Weston 2017) and **doParallel** (Microsoft and Weston 2018).

## 6. Conclusions

The goal of this paper was to introduce the reader to the functionality of the R package **shrinkTVP** (Knaus *et al.* 2019). This R package provides a fully Bayesian approach for statistical

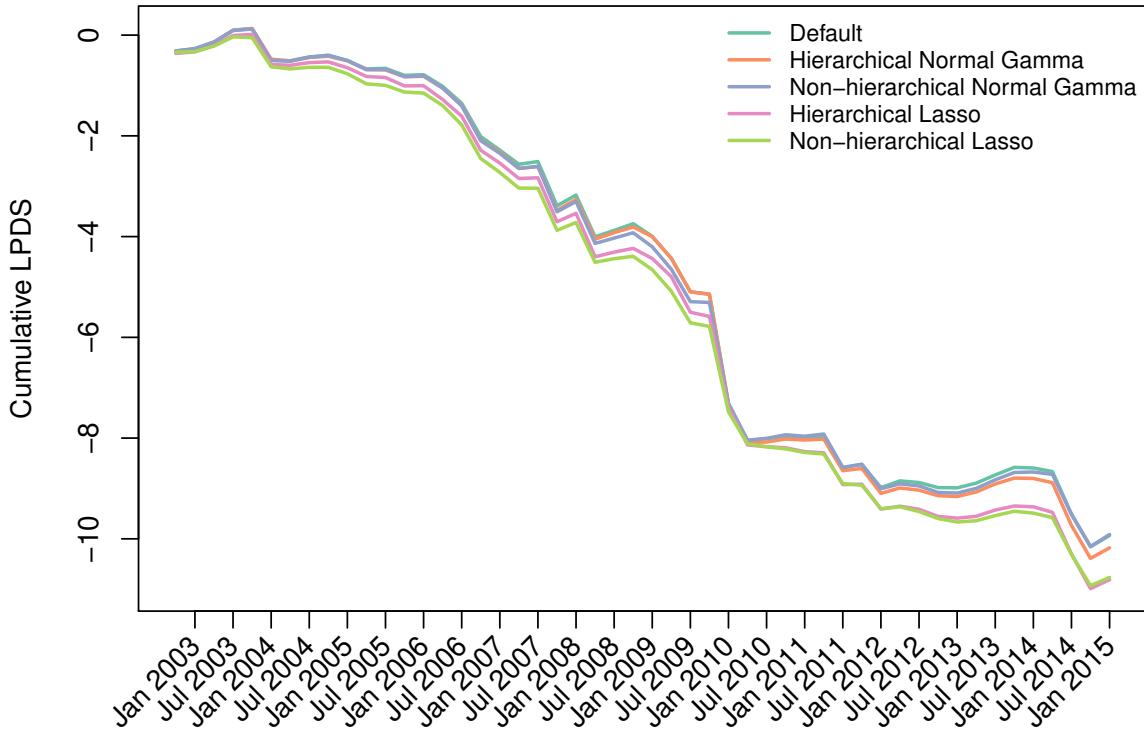

Figure 7: Cumulative LPDSs scores for the last 50 quarters of the `usmacro.update` dataset, for five different shrinkage priors: (1) the full hierarchical shrinkage prior, (2) the hierarchical normal-gamma prior with fixed  $a^\xi = a^\tau = 0.1$ , (3) the normal-gamma prior with  $a^\xi = a^\tau = 0.1$  and  $\kappa^2 = \lambda^2 = 20$ , (4) the hierarchical Bayesian Lasso, and (5) the Bayesian Lasso with  $\kappa^2 = \lambda^2 = 20$ .

inference in TVP models with shrinkage priors. On the one hand, the package provides an easy entry point for users who want to pass on only their data in a first step of exploring TVP models for their specific application context. Running the function `shrinkTVP` under the default model with a fully hierarchical shrinkage prior with predefined hyperparameters, estimation of a TVP model becomes as easy as using the well-known function `lm` for a standard linear regression model. On the other hand, exploiting numerous advanced options of the package, the more experienced user can also explore alternative model specifications such as the Bayesian Lasso and use log-predictive density scores to compare various model specifications.

Various examples of the usage of `shrinkTVP` were given, and the `summary` and `plot` methods for straightforward posterior inference were illustrated. Furthermore, a predictive exercise with the dataset `usmacro.update` from the package `bvars` was performed, with a focus on the calculation of LPDSs using `shrinkTVP`. The default model in `shrinkTVP` showed better performance than its competitors in terms of cumulative LPDSs. While these examples were confined to univariate responses, the package can also be applied in a multivariate context, for instance to the sparse TVP Cholesky SV model considered in Bitto and Frühwirth-Schnatter

(2019), exploiting a representation of this model as a system of independent TVP models with univariate responses.

A plan for further versions of the package is to implement additional shrinkage priors for TVP models such as the well-known horseshoe prior (Bhadra *et al.* 2017).

## A. Appendix: Full conditional distribution of the latent states

Let  $y_t^* = y_t - \mathbf{x}_t\beta$  and  $\mathbf{F}_t = \mathbf{x}_t \text{Diag}(\sqrt{\theta_1}, \dots, \sqrt{\theta_d})$  for  $t = 1, \dots, T$ . Conditional on all other variables, the joint density for the state process  $\tilde{\beta} = (\tilde{\beta}_0, \tilde{\beta}_1, \dots, \tilde{\beta}_T)$  is multivariate normal. This distribution can be written in terms of the tri-diagonal precision matrix  $\Omega$  and the mean vector  $\mathbf{c}$  (McCausland *et al.* 2011):

$$\tilde{\beta} | \beta, \mathbf{Q}, \sigma_1^2, \dots, \sigma_T^2, y_1^*, \dots, y_T^* \sim \mathcal{N}_{(T+1)d}(\Omega^{-1}\mathbf{c}, \Omega^{-1}) \quad (12)$$

where:

$$\Omega = \begin{bmatrix} \Omega_{00} & \Omega_{01} & 0 & & & \\ \Omega_{01}^\top & \Omega_{11} & \Omega_{12} & 0 & 0 & \\ 0 & \Omega_{12}^\top & \Omega_{22} & \Omega_{23} & \ddots & \vdots \\ 0 & \Omega_{23}^\top & \ddots & \ddots & 0 & \\ \vdots & \ddots & \ddots & \Omega_{T-1,T-1} & \Omega_{T-1,T} & \\ 0 & \dots & 0 & \Omega_{T-1,T}^\top & \Omega_{TT} & \end{bmatrix}, \quad \mathbf{c} = \begin{bmatrix} \mathbf{c}_0 \\ \mathbf{c}_1 \\ \mathbf{c}_2 \\ \vdots \\ \mathbf{c}_T \end{bmatrix}.$$

In this representation, each submatrix  $\Omega_{ts}$  is a matrix of dimension  $d \times d$  defined as

$$\begin{aligned} \Omega_{00} &= 2I_d, \\ \Omega_{tt} &= \mathbf{F}_t^\top \mathbf{F}_t / \sigma_t^2 + 2I_d, \quad t = 1, \dots, T-1, \\ \Omega_{TT} &= \mathbf{F}_T^\top \mathbf{F}_T / \sigma_T^2 + I_d, \\ \Omega_{t-1,t} &= -I_d, \quad t = 1, \dots, T, \end{aligned}$$

where  $I_d$  is the  $d \times d$  identity matrix and  $\mathbf{c}_t$  is a column vector of dimension  $d \times 1$ , defined as

$$\mathbf{c}_0 = \mathbf{0}, \quad \mathbf{c}_t = (\mathbf{F}_t^\top / \sigma_t^2) y_t^*, \quad t = 1, \dots, T.$$

In the homoscedastic case,  $\sigma_1^2 = \dots = \sigma_T^2 = \sigma^2$ .

## B. Multicore LPDS calculation

In the code below, the following R packages are used: **doParallel** (Microsoft and Weston 2018), **foreach** (Microsoft and Weston 2017), **zoo** (Zeileis and Grothendieck 2005), and **RhpcBLASctl** (Nakano and Nakama 2018).

```
R> # Calculate LPDS in multicore
R> # Load libraries for multicore computations
R> library("doParallel")
R> library("foreach")
```

```

R>
R> # For manipulating dates
R> library("zoo")
R>
R> # Load library for controlling number of BLAS threads
R> library("RhpcBLASctl")
R>
R> # Define how many periods to calculate LPDS for
R> Tmax <- nrow(us_data) - 1
R> T0 <- Tmax - 49
R>
R> # Determine number of cores to be used and register parallel backend
R> ncores <- 4
R> cl <- makeCluster(ncores)
R> registerDoParallel(cl)
R>
R> lpds <- foreach(t = T0:Tmax, .combine = "cbind",
+   .packages = c("RhpcBLASctl", "shrinkTVP")) %dopar% {
+
+   niter <- 60000
